ABSTRACT: Lysophosphatidylserine (lyso-PS), a lysophospholipid derived from phosphatidylserine (PS), has emerged as a potent signaling lipid in mammalian physiology. *In vivo*, the metabolic serine hydrolases ABHD16A and ABHD12 are major lipases that biosynthesize and degrade lyso-PS, respectively. Of biomedical relevance, deleterious mutations to ABHD12 cause accumulation of lyso-PS in the brain, and this deregulated lyso-PS metabolism leads to the human genetic neurological disorder PHARC (polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract). While the roles of ABHD16A and ABHD12 in lyso-PS metabolism in the mammalian brain are well established, the anatomical and (sub)cellular localizations of both lipases and the functional cross-talk between them with respect to regulating lyso-PS lipids remain under investigated. Here, using subcellular organelle fractionation, biochemical assays, and immunofluorescence-based high-resolution microscopy, we show that the PS lipase ABHD16A is an endoplasmic reticulum-localized enzyme, an organelle intricately regulating cellular PS levels. In addition, leveraging immunohistochemical analysis using genetic ABHD16A and ABHD12 knockout mice as important controls, we map the anatomical distribution of both of these lipases in tandem in the murine brain and show for the first time the distinct localization of these lipases to different regions and cells of the cerebellum. We complement the aforementioned immunohistochemical studies by quantitatively measuring lyso-PS concentrations in various brain regions using mass spectrometry and find that the cerebellar lyso-PS levels are most affected by deletion of ABHD16A (decreased) or ABHD12 (increased). Taken together, our studies provide new insights into lyso-PS signaling in the cerebellum, the most atrophic brain region in human PHARC subjects.

Understanding the molecular, biochemical, and/or metabolic basis of several “orphan” human genetic neurological disorders has been possible only because of the tremendous progress in whole genome sequencing technologies.¹ Following up on these genetic studies, complementary investigations have since revealed that deregulated lipid metabolism is central to a variety of human neurodegenerative disorders.^{2–6} In 2010, a Norwegian family displaying Refsum-like neurological symptoms was clinically investigated, following which their genomes were sequenced.⁷ This genetic study found that this family harbored deleterious (null) mutations to the *abhd12* gene on chromosome 20, which encodes the lipase α/β -hydrolase domain containing protein 12 (ABHD12).⁷ Given the presentation of the symptoms clinically, this new autosomal recessive genetic neurological disorder was termed PHARC (polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract) and deposited in the Online Mendelian Inheritance in Man (OMIM) database (ID 612674).⁸ Since this study, several other genetic studies have mapped mutations (homozygous or compound heterozygous) in the *abhd12* gene, all causing null full-length ABHD12 expression and in turn activity, leading to the symptoms of PHARC.^{9–14} Most human PHARC subjects present with early

onset (early teenage years) visual disturbances (cataract or retinal pigmentation) or hearing loss, with progressively worsening peripheral neuropathy and motor function (*pes cavus*), which eventually manifests into gross cerebellar atrophy.^{8–14} At the time of this discovery, ABHD12 was tentatively annotated as a putative 2-arachidonoyl glycerol (2-AG) lipase, given its *in vitro* ability to hydrolyze the endocannabinoid 2-AG (along with monoacylglycerol lipase and ABHD6),¹⁵ and PHARC was thought to be a genetic neurological disorder caused by defective endocannabinoid metabolism.⁸

In a seminal study to ascertain the biochemical and/or metabolic function of ABHD12, Cravatt and co-workers generated and rigorously characterized the ABHD12 knockout mouse, a murine model of PHARC.¹⁶ Behaviorally, these mice mirror the age-dependent visual, auditory, and motor defects

seen in human PHARC subjects and serve as an excellent preclinical model for investigating various aspects of this neurological disorder. The same study reported that the deletion of ABHD12 had no effect on the brain 2-AG levels,¹⁶ and this meant two things: (i) *In vivo*, ABHD12 hydrolyzed some other lipid, and (ii) PHARC was most likely not a defect in endocannabinoid metabolism. To map the biological pathways regulated by ABHD12 *in vivo*, a comparative mass spectrometry-based untargeted lipidomics experiment termed “discovery metabolite profiling”¹⁷ was performed on the brains of wild type and ABHD12 knockout mice. This study showed that deletion of ABHD12 resulted in a massive accumulation of the signaling lysophosphatidylserine (lyso-PS) lipids in the mouse brain. In the same study, biochemical substrate assays showed that ABHD12 efficiently hydrolyzed lyso-PS lipids *in vitro*, and together, all of these studies conclusively annotated ABHD12 as a lyso-PS lipase¹⁶ (Figure 1). On the basis of the aforementioned findings, Cravatt and co-workers proposed a model for progression of the disease, where as a function of age, the genetic deletion of ABHD12 results in sustained accumulation of lyso-PS in the central nervous system (CNS), which in turn causes neuroinflammation from deregulated lyso-PS signaling, and eventually leads to progressively worsening neurobehavioral (auditory and motor) defects in ABHD12 null mice.¹⁶

Lyso-PS, a potent hormone-like signaling lysophospholipid, is present in all tissues but is most abundant in the CNS (especially the brain) and in immune cells, where it regulates several physiologically important (immuno)biological processes like mast cell degranulation,¹⁸ macrophage activation and clearance of apoptotic cells,^{19–21} facilitation of glucose metabolism in the brain and skeletal muscles,^{22,23} and chemotactic migration and stimulation of human cancer cells.^{24–27} In the CNS, lyso-PS was thought to be biosynthesized from phosphatidylserine (PS) precursors via a PS lipase activity, and inhibitors of such a PS lipase might have tremendous therapeutic importance with respect to restoring the deregulated lyso-PS levels in the CNS and in turn alleviating the pathophysiological effects seen in human PHARC subjects.¹⁶ In search of such an enzyme, another previously unannotated lipase from the metabolic serine hydrolase family,²⁸ ABHD16A, was identified as a principal PS lipase in the CNS and in primary macrophages, where it biosynthesized lyso-PS lipids from PS precursors, and was found to function upstream of ABHD12 in regulating lyso-PS concentrations *in vivo* (Figure 1).²⁹

While the recent annotations of ABHD16A and ABHD12 as the principal PS lipase and lyso-PS lipase in the CNS, respectively, have significantly improved our understanding of lyso-PS metabolism,²⁹ very little is known of the anatomical,

cellular, and subcellular localization of these enzymes in the adult mammalian brain. We recently showed that ABHD12, at a subcellular level, is an integral membrane enzyme localized to the endoplasmic reticulum (ER) membrane in the mammalian brain,³⁰ where it regulates the secretion of very long chain lyso-PS lipids from the ER.^{16,30} Following up on this finding, here, we report that the integral membrane PS lipase ABHD16A is also predominantly localized to the ER membrane in mammalian brain and cells, and we propose a model for the regulation of the flux of lyso-PS across the ER membrane from the interplay of these lipases. In addition, using immunohistochemical analysis, we provide a detailed map of the cell specific anatomical localization of ABHD16A and ABHD12 in the mouse brain, using their respective knockout mice as important controls. Next, using substrate assays, and quantitative lipidomics, we measure PS/lyso-PS lipase activities and lyso-PS concentrations in different brain regions, respectively, and correlate expression patterns to changes in lyso-PS levels following deletion of ABHD16A or ABHD12. Our findings, taken together, provide new insights into the interplay of ABHD16A–ABHD12 and lyso-PS signaling in the adult mammalian brain and a possible explanation of why the cerebellum is the most affected brain anatomical region in human PHARC subjects.

MATERIALS AND METHODS

Materials. Unless otherwise stated, all chemicals, buffers, solvents, and reagents were purchased from Sigma-Aldrich, all lipids and lipid standards were purchased from Avanti Polar Lipids Inc., all tissue culture media, disposables, and consumables were purchased from HiMedia, and all primary and secondary antibodies were purchased from Abcam and Thermo Fisher Scientific, respectively.

Animal Studies. All animal (mouse) studies described in the paper have received formal approval from the Institutional Animal Ethics Committee, IISER Pune (IAEC-IISER Pune), constituted as per the guidelines outlined by the Committee for the Purpose of Control and Supervision of Experiments on Animals (CPCSEA), Government of India. All mice were maintained at the National Facility for Gene Function in Health and Disease (NFGFHD), IISER Pune, and had *ad libitum* access to water and food. All mice used in the study were generated by using a standard heterozygous × heterozygous breeding paradigm, and the mice of the resulting litter were genotyped using previously reported protocols.^{16,29} This breeding paradigm afforded wild type mice with same-sex knockout littermates as controls for all experiments described in this paper.

Subcellular Fractionation Studies. The Neuro-2a cell line was purchased from ATCC and cultured in DMEM

supplemented with 10% (v/v) fetal bovine serum (FBS) and 1% (v/v) penicillin-streptomycin at 37 °C in 5% CO₂ (v/v) unless otherwise mentioned. The Neuro-2a cell line was routinely stained with 4',6-diamidino-4-phenylindole (DAPI) using established protocols to ensure that it was devoid of any mycoplasma contamination.³¹ Subcellular fractionation from tissues (mouse brain) and cells was performed to enrich the nuclear, mitochondrial, microsomal, and cytosolic fractions using a protocol reported by us previously.³⁰ The protein concentration of each subcellular fraction was estimated using Bradford reagent (Sigma-Aldrich), following which the proteome from each fraction was denatured by boiling with 4× sodium dodecyl sulfate (SDS) loading dye at 95 °C for 15 min. This denatured proteome was separated via 10% SDS–polyacrylamide gel electrophoresis (PAGE) and subsequently used for Western blot analysis to assess the purity of enriched fractions and detect the subcellular fraction to which ABHD16A enriches.

Western Blot Analysis. The proteins (typically 50 µg) were resolved on a 10% SDS–PAGE gel, transferred onto a methanol-activated PVDF membrane (GE Healthcare) at 60 V for 12 h at 4 °C, and processed post-transfer using a standard protocol reported by us previously.³² All primary and secondary antibody incubations described here were performed at 1:1000 and 1:10000 dilutions, respectively. The blots were developed using the Thermo West Pico Western blotting substrate (Thermo Fisher Scientific) and visualized on a Syngene G-Box Chemi-XRQ gel documentation system. The following primary antibodies were used in this study: anti-ABHD16A (rabbit, Abcam, 185549), anti-ABHD12 (rabbit, Abcam, ab182011), anti-ATP5A (mouse, Abcam, ab14748), anti-GM130 (mouse, Abcam, ab169276), anti-calnexin (rabbit, Abcam, ab10286), anti-PMP70 (mouse, Sigma-Aldrich, SAB4200181), anti-lamin (rabbit, Cloud Clone Corp., CAF548Hu01), anti-tubulin (rabbit, Cloud Clone Corp., CAB870Hu01), anti-GAPDH (mouse, Cloud Clone Corp., CAB932Hu01), and anti-β-actin (rabbit, Cloud Clone Corp., CAB340Hu01). The following secondary antibodies were used in this study: HRP-conjugated anti-rabbit IgG (goat, Thermo Fisher Scientific, 31460) and HRP-linked anti-mouse IgG (goat, Cloud Clone Corp., SAA544Mu19). All densitometric analyses of bands for quantitative Western blot estimations were performed using ImageJ 1.50i [National Institutes of Health (NIH), for Windows OS].^{33,34}

Lipase Substrate Assays. All PS lipase and lyso-PS lipase substrate assays were performed using established liquid chromatography mass spectrometry (LC-MS) protocols reported previously.³⁰ All lipase assays were performed using 20 µg of proteome on 100 µM lipid substrate (PS substrate, C18:0/18:1 PS; lyso-PS substrate, C18:1 lyso-PS) in a 100 µL final volume for 30 min. All free fatty acids released in these assays from the lipid substrates were detected using an established high-resolution MS method on a Sciex X500R QTOF instrument. The LC and MS parameters were identical to those reported previously.³⁰ All MS data were acquired and analyzed using Sciex-OS software. All quantifications were performed by calculating the area under the curve for the desired fatty acid released and normalizing it to the area under the curve to the internal standard (internal standard, C17:1 free fatty acid; 0.5 nmol per reaction) and the amount of protein used.

Cellular Immunofluorescence Studies. The Neuro-2a cell line was cultured as described previously,^{30,32} and the live

cells were counted using the trypan blue method on a TC20^M automated cell counter (Bio-Rad) following the manufacturer's instructions. A total of 3 × 10⁶ cells were seeded on an 18 mm coverslip in a 35 mm tissue culture dish and processed thereafter using established protocols reported by us previously.^{30,32} All confocal microscopy images were acquired on a Leica SP8 confocal laser scanning microscope fitted with a 63×, 1.4 oil immersion objective. High-resolution microscopy images were obtained on a Leica TCS STED super-resolution microscope with an HC PL APO CS2, 100×, 1.4 oil immersion objective using previously reported protocols.³⁰ All raw images were deconvoluted using Huygens Professional Software (Scientific Volume Imaging BV), and all microscopy images were analyzed using ImageJ 1.50i (NIH, for Windows OS).^{33–35} The following primary antibodies were used in these studies: anti-ABHD16A (rabbit, Abcam, ab1855409), anti-ABHD12 (rabbit, Abcam, ab182011), anti-ATP5A (mouse, Abcam, ab14748, mitochondrial marker), anti-PMP70 (mouse, Sigma-Aldrich, SAB4200181, peroxisome marker), and anti-Sec63A (mouse, Abcam, ab68550, endoplasmic reticulum marker). Goat anti-rabbit IgG (H&L) conjugated with DyLight 488 (Thermo Fisher Scientific, 35553) or goat anti-mouse IgG (H&L) conjugated with Alexa Fluor 568 (Thermo Fisher Scientific, A-11004) was used as the secondary antibody in this immunofluorescence study.

Harvesting Thioglycollate-Elicited Peritoneal Macrophages. Peritoneal macrophages were elicited by injecting 3 mL of 4% (w/v) thioglycollate intraperitoneally using standard protocols reported previously.^{29,31} Three days after injection, peritoneal macrophages were harvested in chilled Dulbecco's phosphate-buffered saline (DPBS) by a peritoneal lavage, and the RBCs from the lavage were separated from the macrophages using RBC lysis buffer. Cells were pelleted at 200g for 3 min and resuspended in RPMI 1640 medium supplemented with 20% (v/v) FBS and 1% (v/v) penicillin-streptomycin (MP Biomedicals). Cells were cultured at 37 °C and 5% CO₂ (v/v) as described above, yielding approximately 15 × 10⁶ cells per mouse. Lipopolysaccharide (LPS) treatment (5 µg/mL) of thioglycollate-elicited peritoneal macrophages was performed for 7 h, and DPBS was used as a vehicle for these treatments. Cellular immunofluorescence and Western blot analysis on primary macrophages were performed as described above.

Immunohistochemical (IHC) Analysis. Mice (10–12 weeks old) were deeply anaesthetized using isoflurane and subsequently perfused first with chilled phosphate-buffered saline (PBS) and then with 4% (w/v) paraformaldehyde (PFA). Brains were dissected gently to maintain anatomical integrity, transferred to 4% (w/v) PFA overnight (~16 h) at 4 °C, and eventually transferred into a 30% (w/v) sucrose solution in PBS until brains sank to the bottom of the tubes (~3 days). Coronal sections (25 µm) were cut on a freezing microtome maintained at −30 °C, and sections were transferred to a reservoir containing ice-cold PBS. For DAB-based bright-field IHC analysis, endogenous peroxidases were first inactivated with 3% (v/v) hydrogen peroxide in PBS for 15 min at 25 °C in the dark. Thereafter, the sections were washed twice with 1% (w/v) bovine serum albumin (BSA) in PBS and subsequently permeabilized with 0.1% (w/v) Triton X-100 and 0.5% (w/v) BSA in PBS for 45 min at 25 °C. The sections were then incubated with the primary antibody in 1% (w/v) BSA overnight at 4 °C, following which the sections were washed three times with 0.5% (w/v) BSA in PBS and incubated with the secondary antibody, biotinylated horse anti-

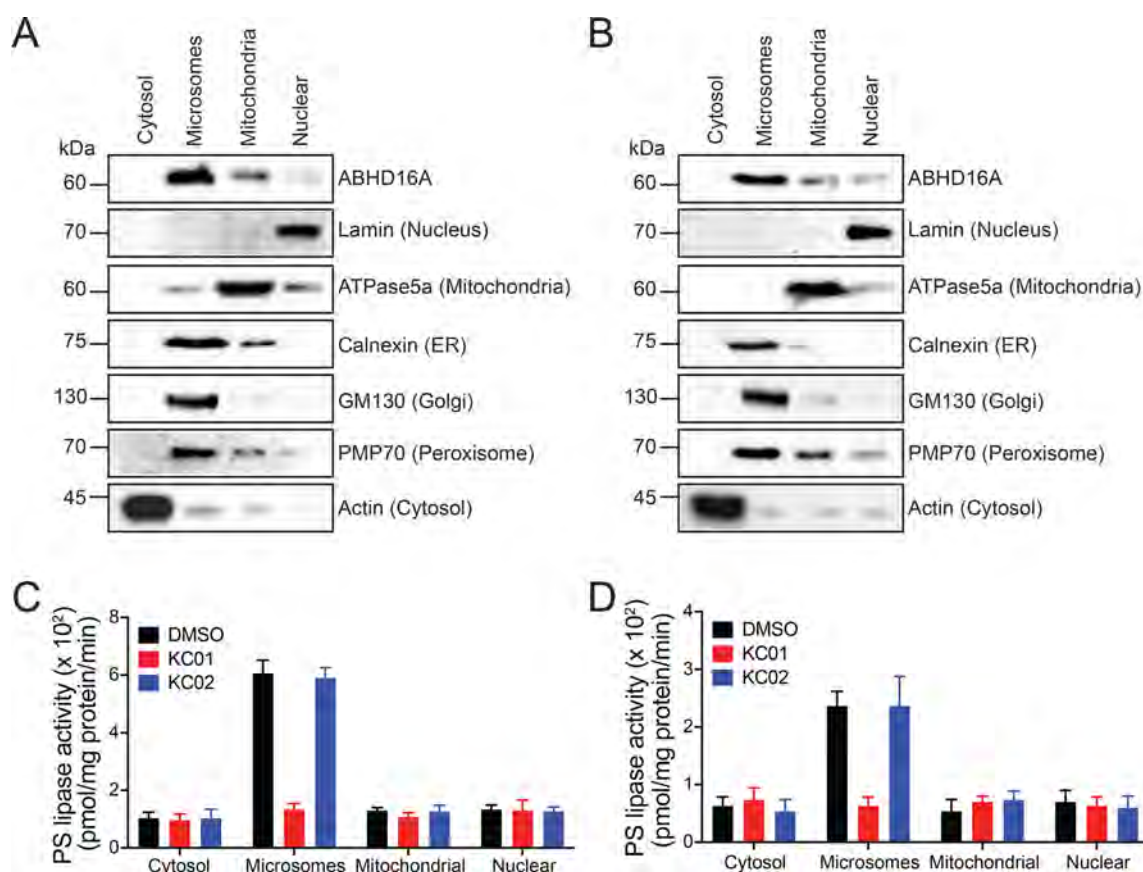

Figure 2. ABHD16A is enriched in the microsomal fraction. Biochemical fractionation of various subcellular organelles from (A) mouse brains, and (B) Neuro-2a cells shows that ABHD16A is enriched in the microsomal fraction. This experiment was repeated three times with reproducible results each time. Consistent with the localization studies, the PS lipase activity is also enriched in the microsomal fractions from (C) mouse brains and (D) Neuro-2a cells. In panels C and D, the PS lipase activity is inhibited by KC01 but not KC02, consistent with this activity coming from ABHD16A. Data represent the mean \pm the standard deviation for three biological replicates per group.

rabbit (Vector laboratories, BP-1100) or biotinylated goat anti-mouse (Vector laboratories, BP-9200) in 0.5% (w/v) BSA in PBS for 1 h at 25 °C. Following this treatment, the sections were washed twice in 0.5% (w/v) BSA in PBS, incubated with ABC Elite Vectastatin (Vector laboratories, PK-6100) for 1 h at 25 °C, and subsequently washed twice with excess PBS. Finally, the sections were stained with ImmPACT DAB (Vector laboratories, SK-4105) for 3 min in the dark, washed with PBS to remove excess DAB, and mounted using VectaMount (Vector laboratories, H-5000). Slides were imaged using an OptraSCAN Desktop or Precipoint M8 Digital Brightfield Microscope. For confocal laser scanning-based IHC analysis, collected sections were directly permeabilized with 0.1% (v/v) Triton X-100 and 0.5% (w/v) BSA in PBS for 45 min at 25 °C and blocked with 1% (w/v) BSA in PBS for 1 h at 25 °C. Thereafter, sections were washed three times with 0.5% (w/v) BSA in PBS and incubated with the primary antibody for 16 h at 25 °C. Sections were washed in 0.5% (w/v) BSA in PBS (three times) and incubated with the secondary antibody (1:1000 dilution) for 1 h at 25 °C. Sections were then washed with PBS and mounted with Fluoromount aqueous mounting medium (Sigma-Aldrich). Slides were imaged using a Leica SP8 confocal laser scanning microscope. The following primary antibodies were used in this study: anti-ABHD16A (rabbit, Abcam, ab185549, 1:100 dilution), anti-ABHD12 (rabbit, Abcam, ab182011, 1:100 dilution), anti-NeuN (mouse, Abcam ab104224, 1:100

dilution), and anti-calbindin (mouse, Abcam, ab82812, 1:50 dilution). The following secondary antibodies were used in this study: goat anti-rabbit IgG (H&L) conjugated with DyLight 488 (Thermo Fisher Scientific, 35553) and goat anti-mouse IgG (H&L) conjugated with Alexa Fluor 568 (Thermo Fisher Scientific, A-11004).

Quantitative Lipid Measurements. Lipids (in particular PS and lyso-PS) were extracted with mass spectrometry grade organic solvents using the Folch extraction method with minor modifications and quantitatively estimated by LC-MS using a protocol previously reported by us.^{31,36} All lipids were quantified using an established multiple-reaction monitoring (MRM-HR) method on a Sciex X500R QTOF instrument.³⁶ Data were acquired and analyzed using Sciex-OS software. All quantifications were performed by calculating the area under the curve for the desired analyte and normalizing it to the area for the respective internal standard (lyso-PS and PS standards for absolute quantification and free fatty acid standard for relative quantifications) and the weight of the tissue or the amount of protein as applicable.

Primary Cerebellar Neuron Culture. Timed pregnancies were set up for wild type C57BL/6J mice, to afford pregnant female mice for harvesting embryos. To obtain an enriched pool of cerebellar neurons, the cerebellum was dissected from day 18 (E18) embryos and minced in DMEM supplemented with 10% (v/v) heat-inactivated FBS and a 1 \times antibiotic-antimycotic solution (Thermo Fisher Scientific). Minced tissue

was digested with 0.25% (w/v) trypsin in PBS for 10 min on ice, following which DNase (0.1 mg/mL in PBS) was added for 5 min on ice. Cells were pelleted down by being spun at 300g for 3 min and washed twice with Hank's Balanced Salt Solution. Cells were then resuspended in neurobasal medium supplemented with a 1× antibiotic-antimycotic solution (Thermo Fisher Scientific), 1× B-27 (Thermo Fisher Scientific), and 1× glutamine (Thermo Fisher Scientific) at 37 °C with 5% (v/v) CO₂. Cells were cultured for 14 days, and the medium was changed every 2 days during this period. The purity of the neurons was confirmed by cellular immunofluorescence by probing for NeuN using established protocols reported above.

Statistical Analysis. All data were plotted, and statistical analysis was performed using GraphPad Prism 7 for Mac OS X software. All bar data are represented as the mean ± the standard deviation (SD) for three or more independent biological replicates per experimental group

RESULTS

Subcellular Localization of ABHD16A. Previous protein deglycosylation studies and the detergent-independent sensitivity of ABHD16A to proteolytic degradation have suggested that ABHD16A is an integral membrane lipase with a cytosolically oriented active site (α/β hydrolase domain)²⁹ (Figure S1). To build on this finding, we first wanted to map the subcellular localization of ABHD16A. To address this, we used the biochemical organelle fractionation along with PS lipase substrate assays, followed by high-resolution microscopy. Using established subcellular fractionation protocols,³⁰ we purified the cytoplasmic, microsomal, mitochondrial, and nuclear fraction from mice brain (Figure 2A) and Neuro-2a cells, an immortalized mammalian neuronal cell line (Figure 2B). In accordance with literature precedent, we confirmed by Western blot analysis that these subcellular fractions were approximately 90% pure by probing for an organelle specific marker (ATPase5a for mitochondria, lamin for the nucleus, calnexin for the ER, PMP70 for peroxisomes, GM130 for the Golgi, and actin for the cytosol). Next, using Western blot analysis, we probed for ABHD16A in all of these subcellular fractions and found in both the mouse brain (Figure 2A) and Neuro-2a cells (Figure 2B) that ABHD16A was most enriched in the microsomal fraction. To corroborate the results from the Western blot experiments, we performed a PS lipase activity assay using C18:0/18:1 PS [stearoyl-oleoyl phosphatidylserine (SOPS)] as a substrate on the different subcellular organelle fractions obtained from the mouse brain and Neuro-2a cells. Consistent with the enrichment of ABHD16A in the microsomal fraction, we found that the specific PS lipase activity was highest in the microsomal fraction obtained from both the mouse brain (Figure 2C) and Neuro-2a cells (Figure 2D) as compared to any other subcellular fraction. The β -lactone KC01 is a potent inhibitor of mammalian ABHD16A, while the β -lactone KC02 serves as a structurally similar inactive control to assay for mammalian ABHD16A activity.^{29,37} When all subcellular fractions were pretreated with KC01 or KC02 (both at 1 μ M, 1 h, 37 °C), we found that the microsomal PS lipase activity in particular was significantly inhibited by KC01, but not KC02, for both the mouse brain (Figure 2C) and Neuro-2a samples (Figure 2D). This result confirmed that the majority of the PS lipase activity from the purified microsomal fraction was indeed coming from

ABHD16A, matching the microsomal enrichment profile for this lipase.

As reported by us previously,³⁰ the microsomal fraction consists mostly of proteins from the ER, peroxisomes, Golgi, and plasma membranes. Given that most of the intracellular PS is localized to the ER, peroxisomal and mitochondrial membrane,³⁸ we hypothesized that ABHD16A would likely be localized to the ER or the peroxisomes. Using high-resolution stimulated emission depletion (STED) microscopy, we found in Neuro-2a cells that ABHD16A co-localizes very well with Sec63a, an ER marker (Figure 3A). In the same cell

Figure 3. ABHD16A is localized to the ER. Cellular immunofluorescence studies in (A) Neuro-2a cells and (B) primary cerebellar neurons show significant co-localization of ABHD16A with Sec63A (an ER marker). Bars on normal images are 5 μ m, while bars on zoomed images are 2 μ m. This experiment was repeated three times with reproducible results each time.

line, we did not find any significant co-localization of ABHD16A with PMP70, a peroxisome marker or ATP5a, a mitochondrial marker, to rule out its presence in ER-mitochondrion contact sites (Figure S2). We have previously shown that mammalian ABHD12 is enriched at the ER membrane,³⁰ and here, we checked for the co-localization of ABHD16A with ABHD12 using STED microscopy. Indeed, we found in Neuro-2a cells that ABHD16A co-localizes with ABHD12, further confirming that ABHD16A is enriched at the ER membrane (Figure S3). To ensure that the cellular localization studies were not an artifact of an immortalized cell line, we generated and cultured primary cerebellar neurons using standard protocols. Here, using STED microscopy, we found that ABHD16A co-localized well with Sec63a, thus confirming the subcellular localization of ABHD16A at the ER membrane even in primary neurons (Figure 3B).

Mapping ABHD16A–ABHD12 Localization in Primary Peritoneal Macrophages upon an Immune Challenge.

Previous large-scale gene expression studies^{39,40} and biochemical characterization of the activities of ABHD16A and ABHD12 in primary peritoneal macrophages (PPMs) elicited using thioglycollate²⁹ have shown that upon lipopolysaccharide (LPS) stimulation (1 μ g/mL, 7 h at 37 °C), the activity of ABHD16A increases (\sim 2.5-fold) while that of ABHD12 decreases (\sim 2-fold), thereby increasing the concentrations of lyso-PS secreted from PPM and enabling the resolution of an inflammatory stimulus.²⁹ However, it is unclear during an inflammatory stimulus whether the subcellular localization of ABHD16A and/or ABHD12 changes, and we wanted to investigate this. Previously, we have reported using cellular immunofluorescence studies that ABHD12 is localized to the

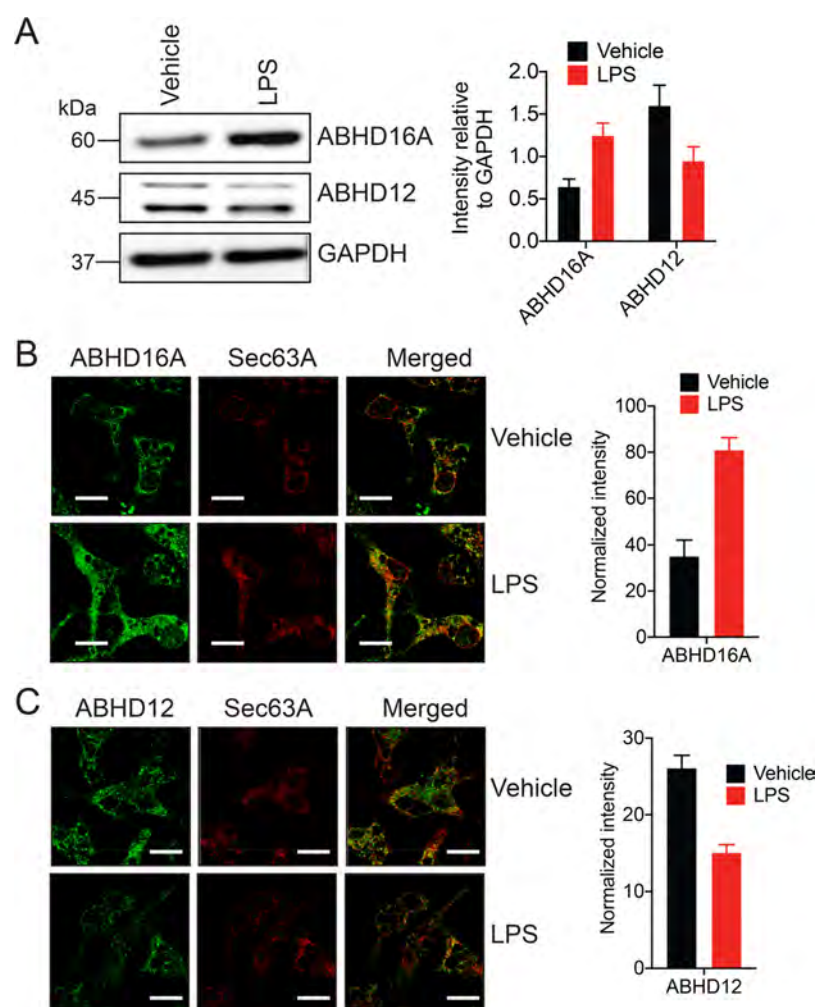

Figure 4. ABHD16A and ABHD12 are ER-localized in primary peritoneal macrophages (PPMs) after an inflammatory stimulus. (A) Representative blot and quantitation from Western blot analysis of PPM, showing an increase and a decrease in ABHD16A and ABHD12 levels, respectively, following LPS treatment. This experiment was performed three times with reproducible results each time. (B and C) Representative images and quantitation from cellular immunofluorescence analysis of PPM, showing an increase and decrease in ABHD16A and ABHD12 levels, respectively, following LPS treatment. This experiment was performed four times with reproducible results each time. Data represent the mean \pm the standard deviation for three or four biological replicates per group. Bars in panels B and C are 5 μ m.

ER in PPM, using PPMs derived from ABHD12 knockout mice as a control for this assay.³⁰ Following up on this study, we first wanted to perform the same study on PPMs obtained from wild type (WT) or ABHD16A knockout mice, to determine the subcellular localization of ABHD16A and to ensure that our immunofluorescence readout of ABHD16A in PPM was accurate. Consistent with findings from the mouse brain and Neuro-2a cells, we found that WT PPM showed ER localization of ABHD16A, and this immunofluorescent signal was significantly diminished in PPM derived from ABHD16A knockout mice (Figure S4).

To validate previous findings, we first assessed by quantitative Western blot analysis the levels of ABHD16A and ABHD12 following LPS treatment of WT PPM (1 μ g/mL, 7 h at 37 $^{\circ}$ C), and found that upon LPS stimulation, the total protein levels (and in turn activity) of ABHD16A and ABHD12 were increased (\sim 2.5-fold) and decreased (\sim 1.8-fold), respectively, relative to a GAPDH loading control (Figure 4A). Having confirmed these changes in the protein level, we next asked if the localization of ABHD16A and/or ABHD12 changed upon LPS stimulation using our established

cellular immunofluorescence assays. We found from this assay that the upon LPS treatment of WT PPM (1 μ g/mL, 7 h at 37 $^{\circ}$ C), the total cellular protein levels of ABHD16A increased >2 -fold (Figure 4B) while that of ABHD12 decreased by \sim 2-fold (Figure 4C), consistent with all previous studies.²⁹ Interestingly, however, we found that for vehicle- or LPS-treated WT PPMs, both ABHD16A and ABHD12 were still predominantly localized to the ER membrane (Figure 4B,C), suggesting negligible changes (if any) in cellular localization upon LPS stimulation.

Mapping the Gross Anatomical Localization of ABHD16A, ABHD12, and Lyso-PS in the Adult Mouse Brain. Having mapped the subcellular localization of ABHD16A and ABHD12 in the mouse brain and in mammalian immortalized and primary cells, we next asked where in the adult mouse brain were both of these lipases maximally enriched. To address this, we first microdissected the different anatomical regions of the brain, namely, the olfactory bulb, prefrontal cortex, cortex, hippocampus, thalamus, and cerebellum, from adult WT mice (10–12 weeks old). We prepared membrane proteomes of these brain

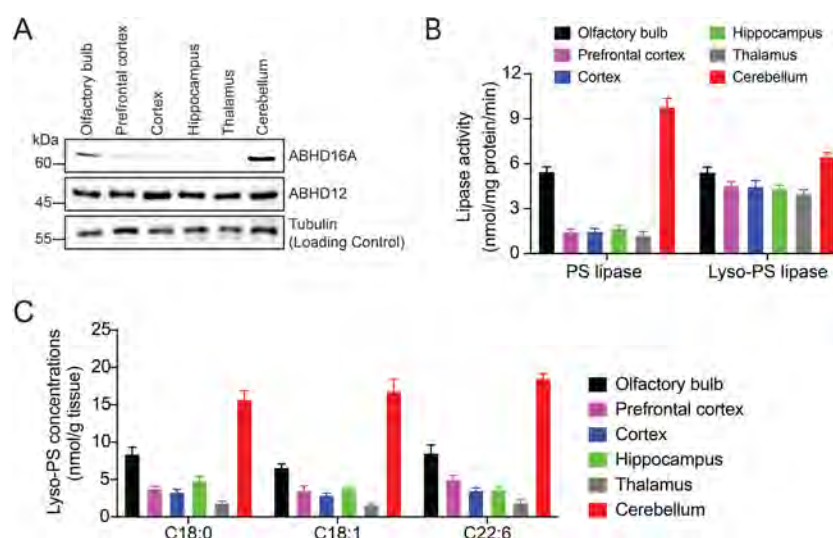

Figure 5. Mapping the brain distribution of ABHD16A, ABHD12, and lyso-PS lipids. (A) Western blot analysis of membrane lysates from different anatomical regions of the brain showing enrichment of ABHD16A in the cerebellum, while ABHD12 is more ubiquitously expressed in the brain. Tubulin was used as a loading control for this experiment. This Western blot analysis was performed three times with reproducible results each time. (B) Lipase activity profiles of membrane lysates from different anatomical regions of the brain showing enrichment of the PS lipase activity in the cerebellum, while lyso-PS lipase activity is comparable across all regions of the brain. Data represent the mean \pm the standard deviation for three biological replicates per group. (C) Quantitative lyso-PS measurements of abundant lyso-PS species (C18:0, C18:1, and C22:6) on different anatomical regions of the brain showing enrichment of these lipids in the cerebellum. Data represent the mean \pm the standard deviation for four biological replicates per group.

regions using standard protocols³⁰ and probed them for ABHD16A and ABHD12 expression using Western blot analysis. We found relative to the tubulin protein loading control that ABHD16A was maximally enriched in the cerebellum and the olfactory bulb, while ABHD12 is ubiquitously expressed at near equal levels in all of the aforementioned brain regions (Figure 5A). Next, we measured the specific PS lipase and lyso-PS lipase activities for the membrane proteomes of the different microdissected brain anatomical regions listed above using standard protocols.³⁰ We found that consistent with the ABHD16A and ABHD12 expression profiles, the specific PS lipase activity was highest in the cerebellum and the olfactory bulb, while the specific lyso-PS lipase activity was nearly equivalent in all brain regions (Figure 5B). In the cerebellum, we confirmed by treatment with a selective inhibitor²⁹ that ABHD16A was indeed contributing to the majority of the PS lipase activity (Figure S5).

To determine if there was any correlation between the expression of ABHD16A and ABHD12 and their respective lipase activities with lyso-PS concentrations in different brain regions, we quantitatively measured abundant lyso-PS lipids (C18:0, C18:1, and C22:6) in the aforementioned microdissected brain regions using established targeted LC-MS.^{16,29} Interestingly, we found that the cerebellum had the highest lyso-PS concentration, followed by the olfactory bulb (2-fold less than the cerebellum), with all other brain regions having near equal lyso-PS concentrations, approximately 4–5-fold lower than that of the cerebellum (Figure 5C). Consistent with ABHD16A being the major lyso-PS biosynthetic enzyme (PS lipase) in the mammalian brain,²⁹ its heightened cerebellar expression (and in turn activity) correlates very well with the cerebellum having the highest lyso-PS concentration in the adult mouse brain. In addition, because ABHD12 expression (and in turn activity) is ubiquitous in the brain, it seems likely that the varying lyso-PS concentrations observed in the

different anatomical regions of the WT adult mouse brain under normal conditions are largely governed by the expression (and in turn activity) of ABHD16A.

To complement these findings, we used two well-established immunohistochemistry methods: a 3,3'-diaminobenzidine (DAB)-based method and the fluorescence-based confocal microscopy method to visualize the localization of ABHD16A and ABHD12 in whole brain sagittal sections. Previous studies of the brains of ABHD12 knockout mice have revealed no anatomical defects,¹⁶ but such a validation study on the brains of ABHD16A knockout mice is currently lacking. To ensure that the loss of ABHD16A activity does not affect the gross brain anatomy, we used Cresyl Violet (Nissl) and Hematoxylin and Eosin (H&E) to stain coronal sections of brains derived from WT and ABHD16A knockout mice and found that the gross anatomy of the brain does not change upon ABHD16A deletion (Figure S6). From the immunohistochemical analysis using their respective knockout mice as controls, we found in sagittal brain sections by both DAB- and immunofluorescence-based staining that consistent with all previous findings, ABHD16A was significantly enriched in the cerebellum compared to any other brain region (Figure 6A), while ABHD12 was more ubiquitous and found enriched in the cerebellum, hippocampus, and cortex (Figure 6B). To ensure that the results from the sagittal sectioning were not artifacts, we also performed DAB staining on coronal sections from WT mice using ABHD16A or ABHD12 knockout mice as controls and found results similar to those of this immunohistochemical study (Figure S7).

Effect of Deletion of ABHD16A or ABHD12 on Lyso-PS and PS Concentrations in Different Anatomical Regions of the Brain. Previous quantitative lipidomic measurements have shown that the deletion of ABHD16A and ABHD12 results in decreased and increased bulk lyso-PS levels in the mammalian brain, respectively.^{16,29} Interestingly, ABHD12 knockout mice brains also show accumulation of

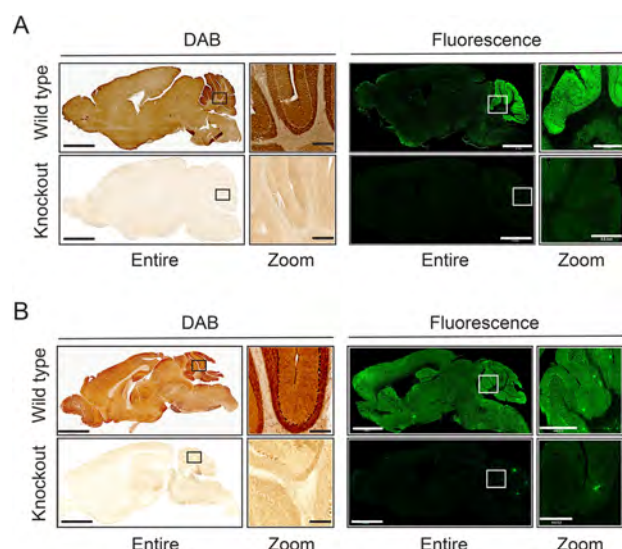

Figure 6. Mapping the anatomical distribution of ABHD16A and ABHD12 using immunohistochemical (IHC) analysis. Representative images from the IHC analysis on sagittal brain sections from (A) wild type and ABHD16A knockout mice and (B) wild type and ABHD12 knockout mice, using DAB staining or immunofluorescence. For both the DAB-based staining and immunofluorescence experiments of the sagittal sections, the left image represents the entire sagittal section while the right image represents a close-up section of the cerebellum. Knockout controls for both IHC analysis show very little signal. Bars on entire sagittal image are 2 mm, while bars on zoomed cerebellar image are 0.5 mm. The IHC experiments were performed four independent times with reproducible results each time.

arachidonoyl (C20:4)-containing PS lipids,¹⁶ recently shown to be through the activation of MBOAT5, a C20:4 specific acyltransferase, that converts excess lyso-PS back to PS,⁴¹ while ABHD16A knockout mice brains show no changes in bulk PS levels.²⁹ Therefore, having mapped the gross anatomical distribution of ABHD16A and ABHD12 in the adult mouse brain, we next examined the effect of deletion of ABHD16A or ABHD12 on the lyso-PS and PS levels in specific anatomical regions of the adult brain. To address this, we again harvested the olfactory bulb, prefrontal cortex, cortex, hippocampus, thalamus, and cerebellum from age- and gender-matched (i) WT and ABHD16A knockout mice or (ii) WT and ABHD12 knockout mice (10–12 weeks old) and measured their relative lyso-PS and PS content using established targeted LC-MS analysis.^{16,29,31}

Consistent with the enriched cerebellar localization of ABHD16A, we found that its deletion resulted in a significant decrease in the levels of all lyso-PS species (especially long chain lyso-PSs) in this brain region (Figure 7A). We also found a modest decrease in the levels of long chain lyso-PSs in the olfactory bulb, where ABHD16A is also enriched, while all other brain regions showed negligible to no changes for the different lyso-PS lipids (Figure 7A). Interestingly, we also found that disruption of ABHD16A resulted in a modest accumulation of a handful of PS lipid species esterified with long chain fatty acids only in the cerebellum, while all other brain regions, including the olfactory bulb, showed little to no change in brain PS profiles (Figure 7B). On the other hand, we found that the deletion of ABHD12 resulted in accumulation of lyso-PS lipids, in particular very long chain lyso-PSs, throughout the brain (Figure 7C). The accumulation of lyso-PSs in ABHD12 knockout mice brains was most profound in

the cerebellum and the olfactory bulb (Figure 7C), consistent with ABHD16A expression, and its role as the principal lyso-PS biosynthetic enzyme in these brain regions. Interestingly, across the different brain regions of ABHD12 knockout mice, we found that levels of several PS lipids were significantly decreased, while those of C20:4-containing PS lipids were elevated (Figure 7D), consistent with previously reported PS measurements from the whole brain.¹⁶ Of note, the deregulation of PS lipids from ABHD12 knockout mice was most pronounced in the cerebellum (Figure 7D).

Mapping the Cell Type Distribution of ABHD16A and ABHD12 in the Cerebellum. Because the cerebellum is the most affected brain region in human PHARC subjects⁸ and because it shows the highest level of lyso-PS deregulation in both ABHD16A and ABHD12 knockout mice, we next wanted to understand the cerebellar localization of both ABHD16A and ABHD12. To address this, we obtained cerebellar (sagittal and coronal) sections from adult WT mice (10–12 weeks old) using their respective knockout mice (ABHD16A or ABHD12) as age- and gender-matched controls and assessed the localization of ABHD16A and ABHD12 using DAB- and fluorescence-based immunohistochemical analysis. In our fluorescence-based immunohistochemical analysis, alongside the antibodies of our lipases of interest (ABHD16A and ABHD12), we used the established anti-NeuN⁴² and anti-calbindin⁴³ antibodies as specific markers for the granular layer neurons and Purkinje neurons, respectively, to assess the specific cerebellar localization of ABHD16A and ABHD12.

From the DAB-based immunohistochemical analysis, we found that ABHD16A is maximally enriched in the granular (and perhaps molecular) layers of the cerebellum but not in the cerebellar ganglionic layer (Figure 8A). We found from the fluorescence-based immunohistochemical analysis that ABHD16A is co-localized with NeuN, but not with calbindin, suggesting that ABHD16A is present in granular neurons, but not in Purkinje neurons (Figure 8B). Though not conclusive from our results, given its expression in the molecular layer from DAB IHC experiments, it is likely that ABHD16A may also be expressed in the parallel fibers of the molecular layer that originate from the granular neurons and synapse with Purkinje neurons. Interestingly, despite the ubiquitous expression of ABHD12 in the adult mouse brain, within the cerebellum, we found by DAB-based immunohistochemical analysis significant enrichment of ABHD12 in the ganglionic layer of the cerebellum (Figure 8C), suggesting that ABHD12 was likely present on Purkinje neurons. Indeed, fluorescence-based immunohistochemical analysis also showed that ABHD12 co-localized with calbindin, but not NeuN, and confirmed that this lipase was localized to Purkinje neurons (Figure 8D). To ensure that the deletion of ABHD16A or ABHD12 did not cause any structural abnormalities in Purkinje neurons, we also assessed cerebellar sections from the respective knockout mice and found by DAB- and fluorescence-based immunohistochemical analysis that the morphology, number, and integrity of Purkinje neurons from knockout mice were nearly identical to those from WT mice (Figure S8). Taken together, these studies show for the first time the discrete localization of ABHD16A and ABHD12 within the cerebellum and suggest for the first time that cerebellar lyso-PS signaling might be paracrine in nature.

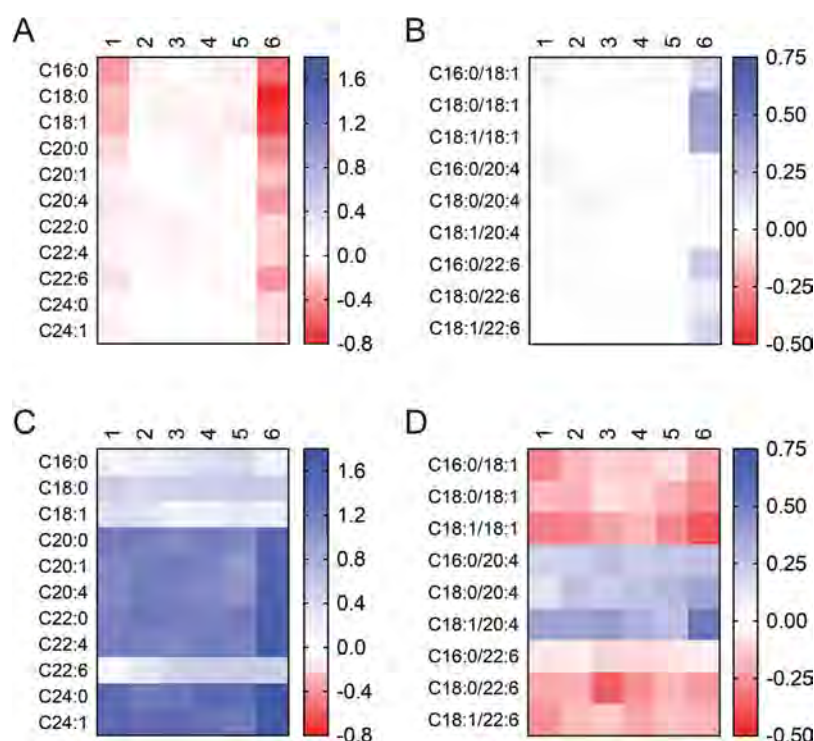

Figure 7. Relative lyso-PS and PS measurements in different brain regions following deletion of ABHD16A or ABHD12. (A) Lyso-PS and (B) PS concentrations in the different regions of the brain of ABHD16A knockout mice relative to corresponding regions from wild type mice. (C) Lyso-PS and (D) PS concentrations in the different regions of the brain of ABHD12 knockout mice relative to corresponding regions from wild type mice. The relative data for each lyso-PS or PS species were obtained by taking the ratio of the knockout value to the wild type value, where the respective value was calculated as an average of four independent biological replicates per genotype. The scale adjoining the heat map plot is log₁₀ (ratio of knockout value to wild type value). The numbers denoted above each heat map plot correspond to different brain regions: 1, olfactory bulb; 2, prefrontal cortex; 3, cortex; 4, hippocampus; 5, thalamus; 6, cerebellum. For the purposes of comparison, panels A and C and panels B and D are plotted on the same logarithmic scale.

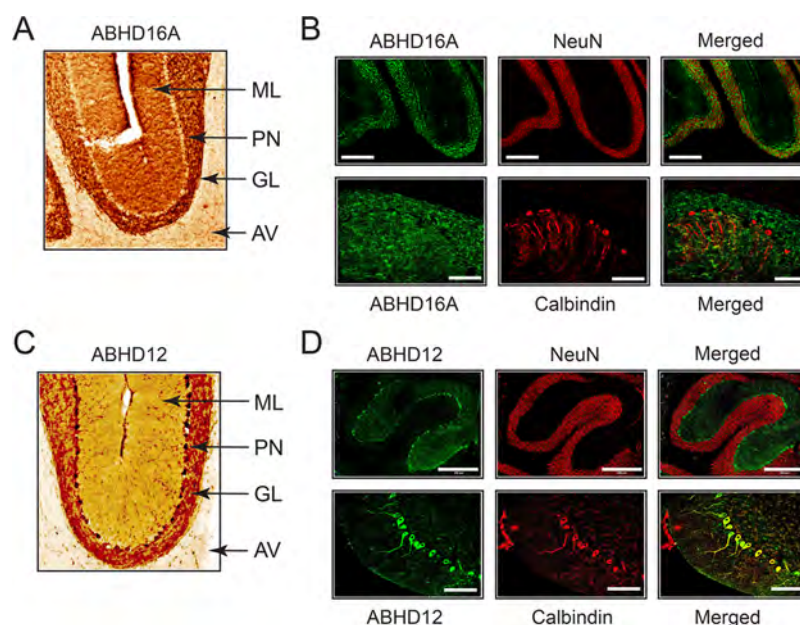

Figure 8. Mapping the anatomical localization of ABHD16A and ABHD12 in the wild type mouse cerebellum. (A) Representative image from DAB-based IHC analysis for ABHD16A in a sagittal cerebellar section. (B) Representative image from fluorescence-based IHC analysis of ABHD16A, in conjunction with NeuN and calbindin. (C) Representative image from DAB-based IHC analysis for ABHD12 in a sagittal cerebellar section. (D) Representative image from fluorescence-based IHC of ABHD12, in conjunction with NeuN and calbindin. Note that images represented in panels A and C were obtained from the sagittal sections of WT mice represented in Figure 6. For panels A and C, ML denotes the molecular layer, PN denotes Purkinje neurons, GL denotes the granular layer, and AV denotes arbor vitae. For panels B and D, bars for the NeuN IHC panel are 300 μ m while bars for the calbindin panel are 100 μ m.

DISCUSSION

Deregulated lipid signaling pathways have been identified as a primary cause of several human neurological diseases,^{2–6} and understanding the biochemical basis for such disorders is important for developing therapies for these diseases. Recently, the early onset progressively debilitating neurodegenerative disease PHARC, caused by deleterious mutations to a gene that encodes the lipase ABHD12, was shown to involve a deregulated lipid signaling pathway, namely lyso-PS.^{8,9,16} The integral membrane serine hydrolase enzyme ABHD12 has been annotated as a principal lyso-PS lipase in the mammalian brain, where it terminates lyso-PS signaling through its lipase activity (Figure 1),¹⁶ and its deletion results in gross accumulation of this lipid class in the CNS, where sustained deregulated signaling causes the pathophysiology of this neurological disease.¹⁶ An upstream PS lipase, ABHD16A, was also recently identified as a principal lyso-PS biosynthetic enzyme in the CNS (Figure 1),²⁹ and inhibitors to this enzyme can in principle reverse the PHARC pathophysiology by preventing lyso-PS biosynthesis. While the biochemical activities of both of these lipases are well understood, their (sub)anatomical and subcellular localizations, and the crosstalk between them, particularly in the brain, remain relatively poorly understood. To understand this, in this paper, using biochemical assays, LC-MS-based lipidomics, cellular immunofluorescence and tissue immunohistochemical analysis, here we set out to map the neuroanatomy of ABHD16A and ABHD12 and improve our current understanding of how this localization likely influences brain lyso-PS distribution and signaling.

First, we show using biochemical subcellular fractionation (Figure 2) and cellular immunofluorescence assays (Figure 3) that the PS lipase ABHD16A, like ABHD12,³⁰ is an ER membrane-localized lipase in the brain and neuronal cells. We also show in PPM, where upon LPS treatment the level of expression (and in turn activity) of ABHD16A increases and that of ABHD12 decreases,²⁹ that the ER localization of both of these enzymes remains unchanged upon this inflammatory stimulus (Figure 4). PS regulates many facets of mammalian physiology, and several studies have shown this in metabolism across various cellular components.^{38,44} PS is synthesized by phosphatidylserine synthase 1 (PSS1) and 2 (PSS2) at mitochondrially associated membranes (MAMs) from other phospholipid precursors and is subsequently fluxed to mitochondria and metabolized to phosphatidylethanolamine (PE) or directly transported from MAMs to the plasma membrane in exchange for phosphatidylinositol 4-phosphate (PIP₄). PS is also transported to the plasma membrane as vesicles through the Golgi network (Figure 9).^{38,44} Quite interestingly, these lipid cell biological studies have also shown that PS is cytosolically oriented across the ER membrane.^{38,44} The fact that ABHD16A is ER localized and has an active site that is cytosolically oriented enables it to access PS on ER membranes to biosynthesize lyso-PS lipids (Figure 9). We hypothesize that while ABHD16A is continually making lyso-PS lipids, a small fraction of this is likely secreted from cells toward homeostatic signaling, while the remaining fraction is metabolized at the ER membrane by the lyso-PS lipase ABHD12 to recycle the headgroup for PS production (Figure 9). Thus, our mapping of ABHD16A here, along with previous reports of ABHD12's ER localization,³⁰ expands our current understanding of PS metabolism in the ER (Figure 9).

Figure 9. Schematic representation of PS metabolism in the ER. The mitochondrially associated membrane (MAM), where PS biosynthesis occurs, is colored purple. Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; PIP₄, phosphatidylinositol 4-phosphate.

Second, we show using immunoblotting, biochemical assays, LC-MS-based lipidomics measurements, and immunohistochemical analysis that PS lipase ABHD16A and the brain's specific PS lipase activity are enriched in the cerebellum, while lyso-PS lipase ABHD12 and the brain's specific lyso-PS lipase activity are ubiquitous (Figures 5 and 6). Given this disparity, lyso-PS lipids are enriched in the cerebellum, where the principal PS lipase ABHD16A resides (Figure 5). Under normal conditions, ABHD16A seems to exert more influence on lyso-PS brain distribution, and we find that deletion of ABHD16A causes a decrease in the levels of lyso-PS lipids and a modest corresponding increase in the levels of PS lipids, only in the cerebellum, while other brain regions mostly remain unaffected by this disruption (Figure 7). On the other hand, given its ubiquitous distribution, we find that deletion of ABHD12 has a more profound influence on lyso-PS and PS lipids in all regions of the brain, with the effects most evident in the cerebellum (Figure 7). The cerebellum is responsible for proper motor functions, posture and balance,^{45–47} all of which are affected in human PHARC subjects,^{8,9} and here, we show that the cerebellum is most susceptible to lyso-PS deregulation upon disruption of ABHD16A and/or ABHD12 activity (Figure 7). Given all of this, and the fact that the cerebellum undergoes maximum atrophy in human PHARC subjects,^{8,9} we wanted to investigate the (sub)anatomical localization of both ABHD16A and ABHD12 in the cerebellum. Interestingly, using IHC analysis, we found that ABHD16A and ABHD12 reside in spatially distinct regions of the cerebellum, i.e., the granular layer neurons and the Purkinje neurons, respectively (Figure 8), that are known to communicate with one another toward regulating normal cerebellar functions.^{45–47}

Figure 10. Preliminary paracrine signaling model for lyso-PS signaling in the cerebellum regulated by ABHD16A and ABHD12 activities.

Although preliminary at this stage, on the basis of the findings reported in this paper, we propose a paracrine signaling model for the role of ABHD16A and ABHD12 and lyso-PS lipids in regulating cerebellar function (Figure 10). We believe that lyso-PS lipids are biosynthesized by ABHD16A rich neuronal cells in the granular layer, following which they are transported by as-of-yet unknown mechanism(s) to the Purkinje layer (and possibly other regions of the brain). Here, Purkinje neurons rich in ABHD12 tightly regulate lyso-PS concentrations and maintain a basal threshold concentration necessary for homeostatic signaling and regulatory activities of the cerebellum (and perhaps other brain regions, too). In the case of PHARC, where ABHD12 activity is absent, this homeostatic threshold is breached, and there is an excess of lyso-PS, constantly stimulating the Purkinje neurons, leading to deregulated cerebellar functioning, eventually manifesting in the motor defects and peripheral neuropathy seen in human PHARC subjects.^{8,9}

With respect to the future, the studies we report here open up several new exciting questions. First, given that the ER is a hub for PS metabolism, understanding the specific contribution of ABHD16A and its dynamic interplay with ABHD12 in regulating PS fluxes within the cellular organelle is a priority. Second, understanding and characterizing the paracrine signaling model for lyso-PS signaling we propose here would provide new mechanistic insights into cerebellar functioning under the influence of this signaling lipid and help in the mapping of pathways downstream of lyso-PS signaling that are deregulated in PHARC. Recently, three G-protein-coupled receptors (GPR34, GPR174, and P2Y10)⁴⁸ and Toll-like receptor 2⁴⁹ have putatively been identified as lyso-PS receptors, and understanding the localization of these receptors in the cerebellum, and characterizing their interplay with ABHD16A, ABHD12, and the lyso-PS network, will likely provide new therapeutic interventions for the treatment of PHARC. Third, it would be important to determine in preclinical models if disrupting ABHD16A activity can indeed rescue or reverse the neurological symptoms seen in PHARC. Fourth, it has been recently shown that ABHD12 also regulates levels of the pro-apoptotic oxidized phosphatidylserine lipids under oxidative stress conditions³¹ and that pharmacological disruption of ABHD12 activity leads to cell death ferroptosis in human cancer cells.^{50–52} It would be interesting to understand whether ferroptosis, if any, contributes to the PHARC pathophysiology and how ABHD12 spatiotemporally regulates oxidized phosphatidylserine lipids in the brain under oxidative

stress. Also, it would be useful to determine whether there are any changes in the brain anatomical distributions of ABHD16A and ABHD12 under an inflammatory stimulus (e.g., systemic LPS treatment) and if and how that contributes to the neurological symptoms of PHARC. Fifth, we find from our profiling study here that ABHD16A is also present in the olfactory bulb, and this expression corroborates the PS lipase activity profiles for the different brain regions. Given the involvement of visual disturbances, i.e., early onset cataract and retinal pigmentation, in human PHARC subjects,^{8,9} the role of lyso-PSs in the development of this pathophysiology should also be investigated. Finally, there is no structural information available for ABHD16A or ABHD12, given that each is an integral membrane protein and difficult to purify and hence crystallize. With the advent of emerging structural biology techniques (e.g., cryo-electron microscopy), determination of the three-dimensional structures of ABHD16A and ABHD12 would enable a better mechanistic understanding of these biomedically important lipases.
